1 INTRODUCTION

Language-constrained path querying [?] is one of techniques for graph navigation querying. This technique allows one to use formal languages as constraints on paths in edge-labeled graphs: path satisfies constraints if labels along it form a word from the specified language.

The utilization of regular languages as constraints, or *Regular Path Querying* (RPQ), is most well-studied and widely spread. RPQs are used for .... Support of RPQs s implemented in !!! Even that, improvement of RPQ algorithm efficiency on huge graphs is an actual problem nowdays. For example, !!!!

At the same time, utilization of more powerful languages, namely context-free languages, gain popularity in the last few years. *Context-Free Path Querying* problem (CFPQ) was introduced by M Yannacacis in 1987 in [?]. A number of

SIGMOD'21, ,

ACM ISBN XXX-X-XXXXX-XXX-X…$15.00

different algoritms was proposed since that time, Context-free is more specific, but actively developing last years.

To make it usable... Integration with graph DB. But recently, in [**?**] J Kujpers et al show that state-of-the-art CFPQ algorithms are not performant enoigh to be used in practice. This fact motivates to finde new algorithms for CFPQ.

Integration with query languages. The problem. We cannot separate regular and context-free queries in general case.

CFPQ as a separated algorithms. Matrix is the fastest.

Moreover, grammar transformation for matrix-based (the fastest existing algorithm) is required, !!!

Linear algebra, GraphBLAS, !!!! is a right way.

Recently, an algortithm was proposed. In this work we improve it, blah-blah-blah

Subcubic CFPQ. Long-time open problem. The best known result is !!!, Also it is shown by Chattergee that !!! For 1-Dyck language : Bradford [**?**]. Can not be generalized to arbitary CFPQ.s We find a way

Contribution

(1) New algorithm. Based on operation over Boolena matrices. All paths semantics. Previous matrix-based solution only single path. For both regualr and context-free path queries.
(2) Correctness and time complexity.
(3) Interconnection between CFPQ and dynamic transitive closure. Conjecture on sublinear dynamic transitive closure and subcubic CFPQ. We show that dynamic transitive closure is a bottleneck on the way to get subcubic CFPQ algorithm.
(4) Evaluation on real-world data. RPQ, CFPQ. Results show that !!!

2 PRELIMINARIES

In this section we introduce basic notation and definitions from graph theory and formal language theory which are used in our work.

2.1 Language-Constrained Path Querying Problem

We use a directed edge-labeled graph as a data model. To introduce the *Language-Constarint Path Querying Problem* [**?**] over directed edge-labeled graphs we should give both language and grammar definitions.

First of all, we introduce edge-labelled diraph $\mathcal{G} = \langle V, E, L \rangle$, where V is a finite set of vertices, $E \in V \times L \times V$ is a finite set of edges, L is a finite set of edge labels. Note that one can always introduce bijection between V and $Q = \{0, \ldots, |V|-1\}$, thus in our work we guess that $V = \{0, \ldots, |V| - 1\}$.

The example of a graph which we will use in further examples is presented in Figure 1.

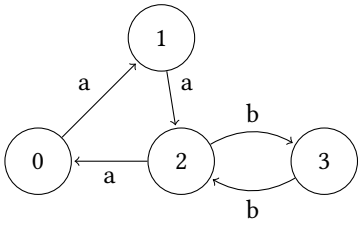

Figure 1: The example of input graph $\mathcal{G}$

Each edge-labeled graph can be represented as an adjacency matrix M: square $|V| \times |V|$ matrix, such that $M[i,j] = \{l \mid e = (i,l,j) \in E\}$. Adjacency matrix M_2 of the graph $\mathcal{G}$ is

$$M_2 = \begin{pmatrix} . & \{a\} & . & . \\ . & . & \{a\} & . \\ \{a\} & . & . & \{b\} \\ . & . & \{b\} & . \end{pmatrix}.$$

In our work we use decomposition of the adjacency matrix to a set of Boolean matrices:

$$\mathcal{M} = \{M^l \mid l \in L, M^l[i,j] = 1 \iff l \in M[i,j]\}.$$

Matrix M_2 can be represented as a set of two Boolean matrices M_2^a and M_2^b where

$$M_2^a = \begin{pmatrix} . & 1 & . & . \\ . & . & 1 & . \\ 1 & . & . & . \\ . & . & . & . \end{pmatrix}, M_2^b = \begin{pmatrix} . & . & . & . \\ . & . & . & . \\ . & . & . & 1 \\ . & . & 1 & . \end{pmatrix} \tag{1}$$

In this way we reduce operations which are necessary for our algorithm from operations over custom semiring (over edge labels) to operations over a Boolean semiring.

Also, we should define the path in the graph and the word formed by the path.

Definition 2.1. Path π in the graph $(G) = \langle V, E, L \rangle$ is a seqence $e_0, e_1, \ldots, e_{n-1}$, where $e_i = (v_i, l_i, u_i) \in E$ and for any e_i, e_{i+1} $u_i = v_{i+1}$. We denote path from v to u as $v \pi u$.

Definition 2.2. The word formed by a path

$$\pi = (v_0, l_0, v_1), (v_1, l_1, v_2), \ldots, (v_{n-1}, l_{n-1}, v_n)$$

is a concatenation of labels along the path: $\omega(\pi) = l_0 l_1 \ldots l_{n-1}$.

The next part is a definitions from the formal language theory.

Definition 2.3. A language $\mathcal{L}$ over a finite alphabet Σ is a subset of all possible sequences formed by symbols from the alphabet: $\mathcal{L}_\Sigma = \{\omega \mid \omega \in \Sigma^*\}$.

Now we are ready to introduce CFPQ problem for the given graph $\mathcal{G} = \langle V, E, L \rangle$ and the given language $\mathcal{L}$ with reachability and all paths semantics.

Definition 2.4. To evaluate context-free path query with reachability semantics is to construct a set of pairs of vertices (v_i, v_j) such that there exists a path $v_i \pi v_j$ in $\mathcal{G}$ which forms the word from the given language:

$$R = \{(v_i, v_j) \mid \exists \pi : v_i \pi v_j, \omega(\pi) \in \mathcal{L}\}$$

Definition 2.5. To evaluate context-free path query with all paths semantics is to construct a set of path π in $\mathcal{G}$ which forms the word from the given language:

$$\Pi = \{\pi \mid \omega(\pi) \in \mathcal{L}\}$$

Note that Π can be infinite, thus in practice, we should provide a way of enumerating such paths with reasonable complexity, instead of explicit construction of the Π.

2.2 Regular Path Queries and Finite State Machine

The first case of language-constrained path querying is *Regular Path Querying* (RPQ): the language L is a regular language. This case is widely spread in practice [**?**].

Usual way to specify regular languages is *regular expressions*. We use the following definition of regular expressions.

Definition 2.6. Regular expression (and regular language) over alphabet Σ can be inductively defined as follows.

- $\varnothing$ (empty language) is regular expression
- ε (empty string) is regular expression
- $a_i \in \Sigma$ is regular expression
- if R_1 and R_2 are regular expressions, then $R_1 \mid R_2$ (alternation), $R_1 \cdot R_2$ (concatenation), R_1^* (Kleene star) are also regular expressions.

For example, one can specify regular expression $R_1 = ab^*$ to find paths in the graph $\mathcal{G}$ (fig. 1). Expected result is set of paths which start with a-labeled edge and contain zero o more b-labeled edges after that.

In this work we use the notion of *Finite-State Machine* (FSM) or *Finite-State Automaton* (FSA) for RPQs.

Definition 2.7. Deterministic Finite-State Machine T is a tuple $\langle \Sigma, Q, Q_s, Q_f, \delta \rangle$ where

- Σ is an input alphabet,
- Q is a finite set of states,
- $Q_s \subseteq Q$ is a set of start (or initial) states,
- $Q_f \subseteq Q$ is a set of final states,
- $\delta : Q \times \Sigma \to Q$ is a transition function.

It is well known, that every regular expression can be converted to deterministic FSM without ε-transitions. To do it one can use []. In our work we use FSM as a representation of RPQ. FSM can be naturally represented by a directed edge-labeled graph: $V = Q$, $L = \Sigma$, $E = \{(q_i, l, q_j) \mid \delta(q_i, l) = q_j\}$, where some vertices have special markers to specify start and final states. Example of graph-style representation of FSM T_1 for the regular expression R_1 is presented in Figure 2.

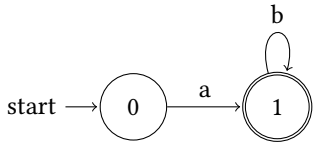

Figure 2: The example of graph representation of FSM for the regular expression ab^*

As a result, FSM also can be represented as a set of Boolean adjacency matrices $\mathcal{M}$ with additional information about start and final vertices. Such representation of T_1 is

$$M^a = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, \; M^b = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

Note, that the edge-labeled graph is an FSM: edges are transitions, all vertices should be both start and final at the same time. Thus RPQ evaluation is an intersection of two FSMs, and the result also can be represented as FSM, because regular languages are closed under intersection.

2.3 Context-Free Path Querying and Recursive State Machines

An even more general case, than RPQ, is a *Context-Free Path Querying Problem (CFPQ)*, where one can use context-free languages as constraints. These constraints are more expressive than the regular ones, for example, one can express classical same-generation query using context-free language, but not a regular one.

Definition 2.8. Context-free grammar $G = \langle \Sigma, N, S, P \rangle$ where Σ is a finite set of terminals (or terminal alphabet), N is a finite set of nonterminals (or nonterminal alphabet), $S \in N$ is a start nonterminal, and P is a finite set of productions (grammar rules) of form $N_i \to \alpha$ where $N_i \in N$, $\alpha \in (\Sigma \cup N)^*$.

Definition 2.9. The sequence $\omega_2 \in (\Sigma \cup N)^*$ is dervable from $\omega_1 \in (\Sigma \cup N)^*$ in one derivation step, or $\omega_1 \to \omega_2$, in the grammar $G = \langle \Sigma, N, S, P \rangle$ iff $\omega_1 = \alpha N_i \beta$, $\omega_2 = \alpha \gamma \beta$, and $N_i \to \gamma \in P$.

Definition 2.10. Context-free grammar $G = \langle \Sigma, N, S, P \rangle$ specifies a *contex-free language*: $\mathcal{L}(G) = \{\omega \mid S \overset{*}{\to} \omega\}$, where $(\overset{*}{\to})$ denotes zero or more derivation steps $(\to)$.

Thus, one can use the grammar $G_1 = \langle \{a, b\}, \{S\}, S, \{S \to a\ b;\ S \to a\ S\ b\} \rangle$ to find paths which form words in the language $\mathcal{L}(G_1) = \{a^n b^n \mid n > 0\}$ in the graph $\mathcal{G}$ (fig. 1).

Regular expressions can be tranformed to a FSM, and a context free grammar can be transformed to *Recursive State*

Machine (RSM) (also known as recursive networks [**?**], recursive automata [**?**], !!!.) in the similar way. In our work we use the following definition of RSM.

Definition 2.11. A recursive state machine R over a finite alphabet Σ is defined as a tuple of elements $(M, m, \{C_i\}_{i \in M})$, where:

- M is a finite set of labels of boxes.
- $m \in M$ is an initial box label.
- Set of *component state machines* or *boxes*, where $C_i = (\Sigma \cup M, Q_i, q_i^0, F_i, \delta_i)$:
  - $\Sigma \cup M$ is a set of symbols, $\Sigma \cap M = \emptyset$
  - Q_i is a finite set of states, where $Q_i \cap Q_j = \emptyset, \forall i \neq j$
  - q_i^0 is an initial state for C_i
  - F_i is a set of final states for C_i, where $F_i \subseteq Q_i$
  - $\delta_i : Q_i \times (\Sigma \cup M) \to Q_i$ is a transition function

RSM behaves as a set of finite state machines (or FSM). Each FSM is called a *box* or a *component state machine* [1]. A box works almost the same way as a classical FSM, but it also handles additional *recursive calls* and employs an implicit *call stack* to *call* one component from another and then return execution flow back.

The execution of an RSM could be defined as a sequence of the configuration transitions, which are done on input symbols reading. The pair (q_i, S), where q_i is current state for box C_i and S is stack of *return states*, describes execution configurations.

The RSM execution starts form configuration $(q_m^0, \langle\rangle)$. The following list of rules defines the machine transition from configuration (q_i, S) to (q', S') on some input symbol a from input sequence, which is read as usual for FSA:

- $(q_i^k, S) \rightsquigarrow (\delta_i(q_i^k, a), S)$
- $(q_i^k, S) \rightsquigarrow (q_j^0, \delta_i(q_i^k, j) \circ S)$
- $(q_j^k, q_i^t \circ S) \rightsquigarrow (q_i^t, S)$, where $q_j^k \in F_j$

Some input sequence of the symbols $a_1 \ldots a_n$, which forms some input word, is accepted, if machine reaches configuration $(q, \langle\rangle)$, where $q \in F_m$. It is also worth noting that the RSM makes nondeterministic transitions, without reading the input character when it *calls* some component or makes a *return*.

According to [1], recursive state machines are equivalent to pushdown systems. Since pushdown systems are capable of accepting context-free languages [4], it is clear that RSMs are equivalent to context-free languages. Thus RSMs suit to encode query grammars. Any CFG can be easily converted to an RSM with one box per nonterminal. The box which corresponds to a nonterminal A is constructed using the right-hand side of each rule for A. An example of such RSM R constructed for the grammar G with rules $S \to aSb \mid ab$ is provided in Figure 3.

Since R is a set of FSMs, it is useful to represent R as an adjacency matrix for the graph where vertices are states from $\bigcup_{i \in M} Q_i$ and edges are transitions between q_i^a and q_i^b with label $l \in \Sigma \cup M$, if $\delta_i(q_i^a, l) = q_i^b$. An example of such adjacency matrix M_R for the machine R is provided in section **??**.

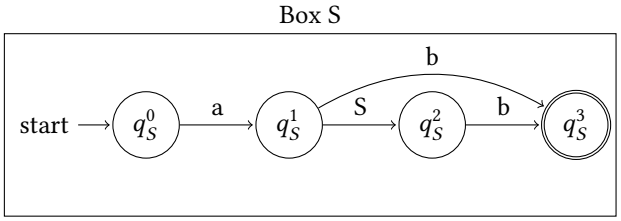

Figure 3: The recursive state machine R for grammar G

Similarly to a FSM, an RSM can be representaed as a graph and, hence, as a set of Boolean adjacency matrices. For our example, M_1 is:

$$M_1 = \begin{pmatrix} . & . & \{a\} & . \\ . & . & \{S\} & \{b\} \\ . & . & . & \{b\} \\ . & . & . & . \end{pmatrix}$$

Matrix M_1 can be represented as a set of Boolean matrices as follows:

$$M_1^S = \begin{pmatrix} . & . & . & . \\ . & . & 1 & . \\ . & . & . & . \\ . & . & . & . \end{pmatrix}, \; M_1^a = \begin{pmatrix} . & . & 1 & . \\ . & . & . & . \\ . & . & . & . \\ . & . & . & . \end{pmatrix}, \; M_1^b = \begin{pmatrix} . & . & . & . \\ . & . & . & 1 \\ . & . & . & 1 \\ . & . & . & . \end{pmatrix}$$

Similarly to an RPQ, a CFPQ is the intersection of the given context-free language and a FSM specified by the given graph. As far as every context-free language is closed under intersection with regular languages, such intersection can be represented as an RSM. Also, one can look at the RSM as a FSM over $\Sigma \cup N$. In this work we use this point of view to propose unified algorithm for evaluation both regular and contex-free path queries with zero overhead for regular ones.

2.4 Graph Kronecker Product

Definition 2.12. Given two edge-labeled directed graphs $\mathcal{G}_1 = \langle V_1, E_1, L_1 \rangle$ and $\mathcal{G}_2 = \langle V_2, E_2, L_2 \rangle$ the Kronecker product of these two graphs is a edge-labeled directed graph $\mathcal{G} = \langle V, E, L \rangle$ where

- $V = V_1 \times V_2$
- $E = \{((u, v), l, (p, q)) \mid (u, l, p) \in E_1 \wedge (v, l, q) \in E_2\}$
- $L = L_1 \cap L_2$

$\mathcal{G}_1 \otimes \mathcal{G}_2$

Adjacency matrix is a tensot ptoduct of adjacency matrices

Definition 2.13. Matrix tensor product definition. !!!!!

Thus, $M(G) = M(G_1) \otimes M(G_2)$ =!!!!

FSM intersection can be calcualeted as tensor product of FSM adjacency matrix.

Example!!!

Using adjacency matrix decompposition we can reduce Tensor product for FSM intersection over Boolean semiring using given definitions.

$$M_1 \otimes M_2 = a \cdot (M_1^a \otimes M_2^a) + b \cdot (M_1^b \otimes M_2^b)$$

In this work we show how to express RSM and FSM intersection in terms of tensor product and transitive closure over Boolean semiring.

3 CONTEXT-FREE PATH QUERYING BY KRONECKER PRODUCT

In this section, we introduce the algorithm for CFPQ which is based on Kronecker product of Boolean matrices. The algorithm provides the ability to solve all-pairs CFPQ in all-paths semantics (according to Hellings [**?**]) and consists of two the following parts.

(1) Index creation. In the first step, the algorithm computes an index which contains information which is necessary to restore paths for specified pairs of vertices. This index can be used to solve the reachability problem without paths extraction. Note that this index is finite even if the set of paths is infinite.
(2) Paths extraction. All paths for the given pair of vertices can be enumerated by using the index computed at the previous step. As far as the set of paths can be infinite, all paths cannot be enumerated explicitly, and advanced techniques such as lazy evaluation are required for implementation. Anyway, a single path can by always extracted by using standard techniques.

We describe both these steps, prove corrctness, and provide time complexity estimations. For the first step we firstly introduce naïve algortihm. Ather that we show how to achieve cubic tyme complexity by using dynamic trensitive closure algorithm and demonstrate that this technoque allow us to get truly subcubic CFPQ algortihm for planar graps.

After thet we provide step-by-step example of query evaluation by using the proposed algorithm.

3.1 Index Creation Algorithm

In this section, we introduce the algorithm for context-free path querying. The algorithm determines the existence of a path, which forms a sentence of the language defined by the input RSM R, between each pair of vertices in the directed edge-labeled graph $\mathcal{G}$. The algorithm is based on the generalization of the FSM intersection for an RSM, and an input graph. Since a graph can be interpreted as a FSM, in which transitions correspond to the labeled edges between vertices of the graph, and an RSM is composed of a set of FSMs, the intersection of such machines can be computed using the classical algorithm for FSM intersection, presented in [4]. Such a way of generalization leads to zero-overhead algorithm for RPQ, contrary to other algorithms which require regular expression to context-free grammar transformation.

The intersection can be computed as a Kronecker product of the corresponding adjacency matrices for an RSM and a graph. Since we are only determining the reachability of vertices, it is enough to represent intersection result as a Boolean matrix. It simplifies the algorithm implementation and allows one to express it in terms of basic matrix operations.

3.1.1 Naïve Version. Listing 1 shows main steps of the algorithm. The algorithm accepts context-free grammar $G = (\Sigma, N, P)$ and graph $\mathcal{G} = (V, E, L)$ as an input. An RSM R is created from the grammar G. Note, that R must have no ε-transitions. M_1 and M_2 are the adjacency matrices for the machine R and the graph $\mathcal{G}$ correspondingly.

Then for each vertex i of the graph $\mathcal{G}$, the algorithm adds loops with non-terminals, which allows deriving ε-word. Here the following rule is implied: each vertex of the graph is reachable by itself through an ε-transition. Since the machine R does not have any ε-transitions, the ε-word could be derived only if a state s in the box B of the R is both initial and final. This data is queried by the $getNonterminals()$ function for each state s.

The algorithm terminates when the matrix M_2 stops changing. Kronecker product of matrices M_1 and M_2 is evaluated for each iteration. The result is stored in M_3 as a Boolean matrix. For the given M_3 a C_3 matrix is evaluated by the $transitiveClosure()$ function call. The M_3 could be interpreted as an adjacency matrix for an directed graph with no labels, used to evaluate transitive closure in terms of classical graph definition of this operation. Then the algorithm iterates over cells of the C_3. For the pair of indices (i, j), it computes s and f — the initial and final states in the recursive automata R which relate to the concrete $C_3[i, j]$ of the closure matrix. If the given s and f belong to the same box B of R, $s = q_B^0$, and $f \in F_B$, then $getNonterminals()$ returns the respective non-terminal. If the the condition holds then the algorithm adds the computed non-terminals to the respective cell of the adjacency matrix M_2 of the graph.

The functions $getStates$ and $getCoordinates$ (see listing 2) are used to map indices between Kronecker product arguments and the result matrix. The Implementation appeals to the blocked structure of the matrix C_3, where each block corresponds to some automata and graph edge.

The algorithm returns the updated matrix M_2 which contains the initial graph $\mathcal{G}$ data as well as non-terminals from N. If a cell $M_2[i, j]$ for any valid indices i and j contains symbol $S \in N$, then vertex j is reachable from vertex i in grammar G for non-terminal S.

Lemma 3.1. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = (\Sigma, N, P)$ be a grammar. Let $\mathcal{G}_k = (V, E_k, L \cup N)$ be graph and M_k its adjacency matrix of the execution some iteration $k \geq 0$ of the algorithm ??. Then for each edge $e = (m, S, n) \in E_k$, where $S \in N$, the following statement holds: $\exists m\pi n : S \rightarrow_G l(\pi)$.*

Proof. (Proof by induction)

Basis: For $k = 0$ and the statement of the lemma holds, since $M_0 = M$, M where is adjacency matrix of the graph G. Non-terminals, which allow to derive ε-word, are also added at algorithm preprocessing step, since each vertex of the graph is reachable by itself through an ε-transition.

Inductive step: Assume that the statement of the lemma holds for any $k \leq (p-1)$ and show that it also holds for $k = p$, where $p \geq 1$.

For the algorithm iteration p the Kronecker product K_p and transitive closure C_p are evaluated as described in the algorithm. By the properties of this operations, some edge $e = ((s, m), (f, n))$ exists in the directed graph, represented by adjacency matrix C_p, if and only if $\exists s\pi' f$ in the RSM graph, represented by matrix M_r, and $\exists m\pi n$ in graph, represented by M_{p-1}. Concatenated symbols along the path π' form some derivation string v, composed from terminals and non-terminals, where $v \rightarrow_G l(\pi)$ by the inductive assumption.

The new edge $e = (m, S, n)$ will be added to the E_p only if s and f are initial and final states of some box B of the RSM corresponding to the non-terminal S_B. In this case, the grammar G has the derivation rule $S_B \rightarrow_G v$, by the inductive assumption $v \rightarrow_G l(\pi)$. Therefore, $S_B \rightarrow_G l(\pi)$ and this completes the proof of the lemma.

□

Lemma 3.2. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = (\Sigma, N, P)$ be a grammar. Let $\mathcal{G}_k = (V, E_k, L \cup N)$ be graph and M_k its adjacency matrix of the execution some iteration $k \geq 1$ of the algorithm ??. For any path $m\pi n$ in graph $\mathcal{G}$ with word $l = l(\pi)$ if exists the derivation tree of l for the grammar G and starting non-terminal S with the height $h \leq k$, then $\exists e = (m, S, n) : e \in E_k$.*

Proof. (Proof by induction)

Basis: Show that statement of the lemma holds for the $k = 1$. Matrix M and edges of the graph $\mathcal{G}$ contains only labels from L. Since the derivation tree of height $h = 1$ contains only one non-terminal S as a root and only symbols from $\Sigma \cup \varepsilon$ as leafs, for all paths, which form a word with derivation tree of the height $h = 1$, the corresponding nonterminals will be added to the M_1 via preprocessing step and first iteration of the algorithm. Thus, the lemma statement holds for the $k = 1$.

Inductive step: Assume that the statement of the lemma hold for any $k \leq (p-1)$ and show that it also holds for $k = p$, where $p \geq 2$.

For the algorithm iteration p the Kronecker product K_p and transitive closure C_p are evaluated as described in the algorithm. By the properties of this operations, some edge $e = ((s, m), (f, n))$ exists in the directed graph, represented by adjacency matrix C_p, if and only if $\exists s\pi_1 f$ in the RSM graph, represented by matrix M_{RSM}, and $\exists m\pi n$ in graph, represented by M_{p-1}.

For any path $m\pi n$, such that exist derivation tree of height $h < k$ for the word $l(\pi)$ with root non-terminal S, there exists edge $e = (m, S, n) : e \in E_k$ by inductive assumption.

Suppose, that exists derivation tree T of height $h = p$ with the root non-terminal S for the path $m\pi n$. The tree T is formed as $S \rightarrow a_1..a_d, d \geq 1$ where $\forall i \in [1..d]$ a_i is sub-tree of height $h_i \leq p - 1$ for the sub-path $m_i\pi_i n_i$. By inductive hypothesis, there exists path π_i for each derivation sub-tree, such that $m = m_1\pi_1 m_2..m_d\pi_d m_{d+1} = n$ and concatenation

of these paths forms $m\pi n$, and the root non-terminals of this sub-trees are included in the matrix M_{p-1}.

Therefore, vertices m_i $\forall i \in [1..d]$ form path in the graph, represented by matrix M_{p-1}, with complete set of labels. Thus, new edge between vertices m and n with the respective non-terminal S will be added to the matrix M_p and this completes the proof of the lemma.

□

Theorem 3.3. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = (\Sigma, N, P)$ be a grammar. Let $\mathcal{G}_R = (V, E_R, L)$ be a result graph for the execution of the algorithm* **??**. *The following statement holds: $e = (m, S, n) \in E_R$, where $S \in N$, if and only if $\exists m\pi n : S \to_G l(\pi)$.*

Proof. This theorem is a consequence of the Lemma 3.1 and Lemma 3.2.

□

Theorem 3.4. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = (\Sigma, N, P)$ be a grammar. The algorithm* **??** *terminates in finite number of steps.*

Proof. The main algorithm *while-loop* is executed while graph adjacency matrix M is changing. Since the algorithm only adds the edges with non-terminals from N, the maximum required number of iterations is $|N| \times |V| \times |V|$, where each component has finite size. This completes the proof of the theorem.

□

3.1.2 Application of Dynamic Transitive Closure. In this subsection we show how to reduce the time complexity of the Algorithm 1 by avoiding redundant calculations.

It is easy to see that the most time-consuming steps in the Algorithm 1 are the Kronecker product and transitive closure computations. Recall that the matrix M_2 is always changed in incremental manner i. e. elements (edges) are added to M_2 (and are never deleted from it) on every iteration of the Algorithm 1. So one does not need to recompute the whole product or transitive closure if an appropriate date structure is maintained.

To deal with the Kronecker product computation, we use the left-distributivity of the Kronecker product. Let A_2 be a matrix with newly added elements and B_2 be a matrix with the all previously found elements, such that $M_2 = A_2 + B_2$. Then by the left-distributivity of the Kronecker product we have $M_1 \otimes M_2 = M_1 \otimes (A_2 + B_2) = M_1 \otimes A_2 + M_1 \otimes B_2$. Notice that $M_1 \otimes B_2$ is known and is already in the matrix M_3 and its transitive closure also is already in the matrix C_3, because it was calculated on the previous iterations, so it is left to update some elements of M_3 by computing $M_1 \otimes A_2$, which can be done in $O(|A_2||M_1|)$ time, where $|A|$ denotes the number of non-zero elements in a matrix A.

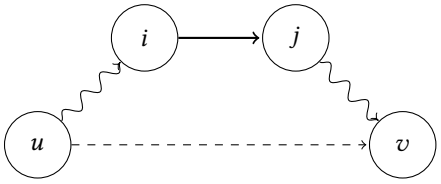

Figure 4: The vertex j become reachable from the vertex u after the addition of edge (i, j). Then the vertex v is reachable from u after inserting the edge (i, j) if v is reachable from j.

The fast computation of transitive closure can be obtained by using incremental dynamic transitive closure technique. We use an approach by Ibaraki and Katoh [5] to maintain dynamic transitive closure. The key idea of their algoritm is to recalculate reachability information only for those vertices, which become reachable after insertion of the certain edge (see Figure 4 for details). The algorithm is presented in Listing 3 (we have slightly modified it to efficiently track new elements of the matrix C_3).

Listing 3 The dynamic transitive closure procedure

```
1:  function ADD(C3, i, j)
2:      n ← Number of rows in C3
3:      C3' ← Empty matrix of size n × n
4:      for u ≠ 0 ∈ checkCondition(C3, i, j) do
5:          newReachablePairs(C3, C3', u, j)
6:      return C3'
7:  function CHECKCONDITION(C3, i, j)
8:      A ← Empty array of size n
9:      for u ∈ 0...n | u ≠ j do    ▷ 1 ∧ 1 = 0 ∧ 0 = 1 ∧ 0 = 0; 0 ∧ 1 = 1
10:         A[u] = C3[u, j] ∧ C3[u, i]
11:     return A
12: function NEWREACHABLEPAIRS(C3, C3', u, j)
13:     C3'[u, v] = C3[u, v] ∧ C3[j, v]        ▷ 1 ∧ 1 = 0 ∧ 0 = 1 ∧ 0 = 0;
    0 ∧ 1 = 1
```

Final version of the modified Algorithm 1 is shown in Listing 4.

Theorem 3.5. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = (\Sigma, N, P)$ be a grammar. The Algorithm 4 calculates a result graph $\mathcal{G}_R = (V, E_R, L)$ in $O(n^3)$ time.*

Proof. Let $|A|$ be a number of non-zero elements in a matrix A. Consider the total time which is needed for computing the Kronecker products. The elements of the matrices $A_2^{(i)}$ are pairwise distinct on every i-th iteration of the Algorithm therefore we have $\sum_i T(M_1 \otimes A_2^{(i)}) = |M_1| \otimes \sum_i |A_2^{(i)}| = |M_1|O(n^2)$ operations in total.

Now we derive the time complexity of maintainig the dynamic transitive closure. Notice that C_3 has size of $O(n^2)$ so no more than $O(n^2)$ edges will be added during all iterations

Listing 4 Kronecker product based CFPQ using dynamic transitive closure

```
1:  function contextFreePathQuerying(G, 𝒢)
2:      R ← Recursive automata for G
3:      M_1 ← Adjacency matrix for R
4:      M_2 ← Adjacency matrix for 𝒢
5:      A_2 ← Adjacency matrix for 𝒢
6:      C_3 ← The empty matrix
7:      for s ∈ 0..dim(M_1) − 1 do
8:          for i ∈ 0..dim(M_2) − 1 do
9:              M_2[i, i] ← M_2[i, i] ∪ getNonterminals(R, s, s)
10:     while Matrix M_2 is changing do
11:         M'_3 ← M_1 ⊗ A_2
12:         A_2 ← The empty matrix of size n × n
13:         for M'_3[i, j] | M'_3[i, j] = 1 do
14:             C_3[i, j] ← 1
15:             C'_3 ← ⋃_(i,j) add(C_3, i, j)        ▷ Updating the transitive closure
16:             C_3 ← C_3 + C'_3
17:         n ← dim(M_3)
18:         for (i, j) | C'_3[i, j] ≠ 0 do
19:             s, f ← getStates(C'_3, i, j)
20:             if getNonterminals(R, s, f) ≠ ∅ then
21:                 x, y ← getCoordinates(C'_3, i, j)
22:                 M_2[x, y] ← M_2[x, y] ∪ getNonterminals(R, s, f)
23:                 A_2[x, y] ← A_2[x, y] ∪ getNonterminals(R, s, f)
24:     return M_2
```

of the Algorithm. The function *checkCondition* from the Listing 3 takes $O(n)$ time for every inserted edge (i, j). Thus we have $O(n^2 n) = O(n^3)$ operations in total. The function *newReachablePairs* requires $O(n)$ time for a given vertex u. This operation is performed for every pair (j, v) of vertices such that a vertex j became reachable from the vertex u. The vertex j become reachable from the vertex u (and accordingly the value of the matrix cell $C_3[u, j]$ becomes 1 from 0) only once during the entire computation, so the function *newReachablePairs* will be executed at most $O(n^2)$ times for every u and hence $O(n^3)$ times in total for all vertices. Therefore $O(n^3)$ operations are performed to maintain dynamic transitive closure during all iteration of the Algorithm 4.

Notice that the matrix C'_3 contains only new elements, therefore C_3 can be updated derectly using only $|C'_3|$ operations and hence $O(n^2)$ operations in total. The same holds for cycle in line 18 of the Algorithm 4, because operations are performed only for non-zero elements of the matrix $|C'_3|$. Finally, we have that the time complexity of the Algorithm 4 is $O(n^2) + O(n^3) + O(n^2) + O(n^2) = O(n^3)$. □

3.1.3 Speeding up by a factor of $\log n$. In this subsection we use the Four Russians' trick to speed up the dynamic transitive closure algorithm from the Listing 3.

Theorem 3.6. *The computation of transitive closure matrices can be done in $O(n^3/\log n)$ time when n^2 edges are added to the graph.*

Proof. Consider the function *checkCondition* from the Listing 3. Its operations are equivalent to the element-wise (Hadamard) product of two vectors of size n, where multipication operation is denoted as $\wedge$ and has the following properties: $1 \wedge 1 = 0 \wedge 0 = 1 \wedge 0 = 0$ and $0 \wedge 1 = 1$. The first vector represents reachability of a given vertex i from other vertices $\{u_1, u_2, ..., u_n\}$ of the graph and the second vector represents the same for a given vertex j. The function *newReachablePairs* also can be reduced to the computation of the Hadamard product of two vectors of size n for a given u_k. The first vector contains the information whether vertices $\{v_1, v_2, ..., v_n\}$ of the graph are reachable from a given vertex u_k and the second vector represents the same for a given vertex j. The element-wise product of two vectors can be calculated naively in time $O(n)$ which gives the $O(n^3)$ time for maintaining the transitive closure. Thus, the time complexity of the transitive closure can be reduced by speeding up element-wise product of two vectors of size n.

To achive this goal, we use the Four Russians' trick. Split each vector into $n/\log n$ parts of size $\log n$. Create a table S such that $S(a, b) = a \wedge b$ where $a, b \in \{0, 1\}^{\log n}$. This takes a time $O(n^2 \log n)$, since there are $2^{\log n} = n$ variants of boolean vectors of size $\log n$ and hence n^2 pairs of vectors (a, b) in total, and each component takes $O(\log n)$ time. With table S, we can calculate product of two parts of size $\log n$ in constant time. There are $n/\log n$ such parts, so the element-wise product of two vectors of size n can be calculated in time $O(n/\log n)$ with $O(n^2 \log n)$ preprocessing. This gives us a dynamic transitive closure algorithm running in time $O(n^3/\log n)$: both of the functions *checkCondition* and *newReachablePairs* are evaluated no more than $O(n^2)$ times during the whole computation, and each function calculates Hadamard product of two vectors in $O(n/\log n)$ time. □

Notice that the maintaining of the dynamic transitive closure dominates the cost of the Algorithm 4, therefore we immediatly deduce the following.

Corollary 3.7. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = (\Sigma, N, P)$ be a grammar. The result graph $\mathcal{G}_R = (V, E_R, L)$ can be calculated in $O(n^3/\log n)$ time.*

Subcubic for planar graphs using [7].

Cojecture on sublinear dynamic transitive closure and subcubic CFPQ.

3.2 Paths Extraction Algoritm

After index created one can enumerate all paths between cpecified vertices.

Algorithm is presented in Listing 5.

Ideas and description.

Correcness.

Listing 5 Paths extraction algorithm

```
1:  C_3 ← result of index creation algorithm: final transitive closure
2:  M_1 ← the set of adjacency matrices of the input RSM
3:  M_2 ← the set of adjacency matrices of the final graph
4:  function getPaths(v_s, v_f, N)
5:      q_N^0 ← Start state of automata for N
6:      F_N ← Final states of automata for N
7:      res ← ⋃_{f∈F_N} getPathsInner((q_N, v_s), (f, v_f))
8:      return res
9:  function getSubpaths((v_i, s_i), (v_j, s_j), (v_k, s_k))
10:     l ← {(v_i, t, v_k) | M_2^t[s_i, s_k] ∧ M_1^t[v_i, v_k]}
            ∪ ⋃_{N | M_2^N[s_i, s_k]} getPaths(v_i, v_k, N)
            ∪ getPathsInner((v_i, s_i), (v_k, s_k))
11:     r ← {(v_k, t, v_j) | M_2^t[s_k, s_j] ∧ M_1^t[v_k, v_j]}
            ∪ ⋃_{N | M_2^N[s_k, s_j]} getPaths(v_k, v_j, N)
            ∪ getPathsInner((v_k, s_k), (v_j, s_j))
12:     return l · r
13: function getPathsInner((v_i, s_i), (v_j, s_j))
14:     parts ← {(v_k, s_k) | C_3[(v_i, s_i), (v_k, s_k)] = 1 ∧
        C_3[(v_k, s_k), (v_j, s_j)] = 1}
15:     return ⋃_{(v_k,s_k)∈parts} getSubpaths((v_i, s_i), (v_j, s_j), (v_k, s_k))
```

Time complexity of single path extraction. Paths enumeration complexity.

3.3 An example

In this section we introduce detailed example to demonstrate steps of the proposed algorithm. Our example is based on the classical worst case scenario introduced by Jelle Hellings in [**?**]. Namely, let we have a graph $\mathcal{G}$ presented in figure 1 and the RSM R presented in figure [**?**].

First step we represent graph as a set of boolean matrices as presented in 1, and RSM as a set of boolean matrices, as presented in **??**. Note, that we should add new empty matrix M_2^S to M_2. After that we should iteratively compute M_1 and C.

First iteration. As far as $M_2^{S,0}$ is empty (no edges with lable S in the input graph), then correspondent block od the Kronecker product will be empty.

$M_3^1 = M_1^a \otimes M_2^{a,0} + M_1^b \otimes M_2^{b,0} + M_1^S \otimes M_2^{S,0} =$

(0,3)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(1,0)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(1,1)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(1,2)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	1
(1,3)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	1	.
(2,0)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(2,1)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(2,2)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	1
(2,3)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	1	.
(2,0)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(2,1)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(2,2)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.
(2,3)	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.	.

This path starts in the vertex $(0, 1)$ and finishes in the vertex $(3, 3)$. We can see, that 0 is a start state of RSM R and 3 is a final state of RSM R. Thus we can conclude that there esists a path between vertices 1 and 3 such that respective word is acceptable by R. As a result we can add the edge $(1, S, 3)$ to the $\mathcal{G}$, namely we should update the matrix M_2^S.

Second iteration. Modified input graph contains edge with lable S. From now !!!

Result is presented in figure 5. New edges is added to the original graph.

Index creation is finished. Onw can use it to unswer reachcbility queryes, but for some problems it is necessary to restore

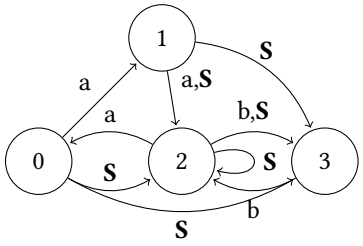

Figure 5: The result graph $\mathcal{G}$

```
getPaths(2, 2, S)
└ getPathsInner(2, 14)
  ├ parts= {4}
  └ getSubpaths(2, 14, 4)
    ├ l={2 -a-> 0}
    │ └ ...
    │   └ getPathsInner(0, 14)
    │     ├ parts = {5, 11}
    │     └ getSubpaths(0, 14, 5)
    │       ├ ...
    │       │ └ getPaths(1, 3, S)
    │       │   └ ...
    │       │     └ getSubpaths(1,15,6)
    │       │       ├ l = {1 -a-> 2}
    │       │       ├ r = {2 -b-> 3}
    │       │       └ return {1 -a-> 2 -b-> 3}
    │       └ getSubpaths(0, 14, 11)
    │         ├ ...
    │         │ └ getPaths(1, 3, S) // An alternative way to get paths
    │         │                       from 1 to 3 which leads to
    │         │                       infinite set of paths
    │         │   return r_∞^{1↝3} // An infinite set of path from 1 to 3
    │         └ ...
    │         return {0 -a-> 1 -a-> 2 -b-> 3 -b-> 2} ∪ ({0 -a-> 1} · r_∞^{1↝3} · {3 -b-> 2})
└ return {2 -a-> 0 -a-> 1 -a-> 2 -a-> 0 -a-> 1 -a-> 2 -b-> 3 -b-> 2 -b-> 3 -b-> 2 -b-> 3 -b->
  2} ∪ ({2 -a-> 0 -a-> 1 -a-> 2 -a-> 0 -a-> 1} · r_∞^{1↝3} · {3 -b-> 2 -b-> 3 -b-> 2 -b-> 3 -b-> 2})
```

Figure 6: Example of call stack trace

paths. One can do it by using index created. Let for example we try to restore path from 2 to 2 derived from S.

To do it one should call `getPaths(2, 2, s)`. Partial trace of this call is presented below in figure 6. First, we convert vertices from grap to indeces in matrix and call `getPathsInner`. Separation vertex `pats={4}` and try to get patrs of paths going throw vertex with $id = 4$.

Expected path is returned, other paths calcualtion

Lazy evaluation is required.

The paths enumeration problem is actual here: ho can we enumerate paths with small delay.

4 IMPLEMENATION DETAILS

Naïve algortihm is implemented (without dynamic transitive closure).

Linear algebra, GraphBLAS, parallel CPU.

Specific details. Sparsity parameters. How to express some steps efficiently.

Integration with RedisGraph.

Grammar is a file.

On paths extraction algorithm. I think that we shuold implement single path extraction, and paths without recursive calls. Lazy evalustion is not good idea for C implementation.

5 EVALUATION

Questions.

(1) Compare classical RPQ algorithms and our agorithm
(2) Compare other CFPQ algorithms and our algorithms
(3) Ivestigate effect of grammar optimization

5.1 RPQ

In oder to do smthng....

Dataset description, tools selection.

5.1.1 Dataset. Dtatset for evalustion

We evaluate our solution on RPQs We choose templates of the most popular RPQs which are presented in table **??** We generate !!! queryes for each template.

5.1.2 Results. Results of evalustion

Index creation.

Paths extraction

5.1.3 Conclusion.

5.2 CFPQ

Comparison with matrix-based algorithm.

5.2.1 Dataset. Dtatset for evalustion. It should be CFPQ_Data[1].

Same-generation queryes, memory aliases.

5.2.2 Results. Results of evaluation.

Index creation.

Paths extraction.

5.2.3 Conclusion.

5.3 Grammar transformation

On query optimization.

Memory aliases.

Synthetic???

6 RELATED WORK

Language constrained path querying is a whide area !!!!

RPQ algorithms: derivatives [**?**], Glushkov [**?**], etc.!!!! [**?**] distributed, not lnear algebra.

CFPQ algorithms: Hellings [**?**], Bradford [2], Azimov [**?**], Verbitskaya [**?**], Ciro [**?**], form static code analysis [**?**],

[1] !!!!

Subcubic CFPQ: Bradford, Chattergee, For trees — partial cases, RSM-s — 4 Russians method, Smth else?

Dynamic transitive closure [**?**] [**?**] [**?**] [**?**] algebraic, combinatorial, special graph types.

Implementation side. Linear algebra based approcges to evaluate queryes (datalog, SPARQL, etc) [**?**] Not focused ot types of queryes. Matrices, !!!! SPARQL !!!! Datalog !!!!

7 CONCLUSION AND FUTURE WORK

!!!! Was presented. Evaluation demonstartes that!!! The way to solve teoretical problem is provided.

Subcubic CFPQ in general case — sublinear transitive closure.

On RSM optimization and query optimization. RSM minimization, ther transformations.

We evaluate naïve implemantation. Try to use advanced algorithms for dynamic transotive closure [3].

HiCOO format [**?**] for distributed processing of huge graphs.

GPGPU-based implementation. Multi-GPU version. Unified memory, etc [**?**]

Full integration with Graph DB. For example, with RedisGraph. SuiteSparse as abse and success of matrix algorithm integration [**?**]

Other semantics: shortest path, simple path and so on. Weighted graphs.

Streaming graph querying. Both regular [6] and context-free.

Specialization on query. Algebraic opersations specialization (partially static data in Haskell [**?**]). Runtime specialization (Posgres) [**?**]
