

¹Specification of regular constraints in SPARQL propert paths: <https://www.w3.org/TR/sparql11-property-paths/>. Access date: 07.07.2020.

problem nowadays, and new algorithms and solutions are being created [23, 27].

At the same time, utilization of more powerful languages, namely context-free languages, gain popularity in the last few years. *Context-Free Path Querying* problem (CFPQ) was introduced by Mihalis Yannakakis in 1990 in [28]. A number of different algorithms was proposed since that time, but recently, in [19] Jochem Kuijpers et al. show that state-of-the-art CFPQ algorithms are not performant enough to be used in practice. This fact motivates to find new algorithms for CFPQ.

One of the promising ways to achieve high-performance solutions for graph analysis problems is to reduce graph algorithms to linear algebra. This way, the description of basic linear algebra primitives, the GraphBLAS [17] API, was proposed. Solutions that use libraries that implement this API, such as SuiteSparse [12] and CombBLAS [8], show that reduction to linear algebra is a way to utilize high-performance parallel and distributed computations for graph analysis.

Rustam Azimov in [3] shows how to reduce CFPQ to matrix multiplication. Later, in [22] and [25], it was shown that utilization of appropriate libraries of linear algebra for Azimov's algorithm implementation allows one to get practical solution for CFPQ. But Azimov's algorithm requires transforming the input grammar to Chomsky Normal Form, which leads to the grammar size increase, thus worsen performance especially for regular queries and complex context-free queries.

To solve these problems, recently, an algorithm based on automata intersection was proposed [?]. This algorithm is based on linear algebra and does not require the input grammar transformation. In this work we improve it. First of all, we reduce it to operations over Boolean matrices, thus simplify its description and implementation. Also, we show that this algorithm is performant enough for regular queries, so it is a good candidate for integration with real-world query languages: we can use one algorithm to evaluate both regular and context-free queries.

Moreover, we show that this algorithm is a way to attack a long-standing problem of subcubic CFPQ. The best-known result for the general case is an $O(n^3/\log n)$ algorithm of Swarat Chaudhuri [10]. Also, there are solutions for partial cases. For example, there is a truly subcubic algorithm for 1-Dyck language proposed by Phillip Bradford [7]. But this solution cannot be generalized to arbitrary CFPQs. So, in our knowledge, there is no truly subcubic general algorithm for CFPQs. In this work we show that incremental transitive closure is a bottleneck on the way to get subcubic time complexity for CFPQ.

To summarize, we make the following contributions in this paper.

- (1) We rethink and improve tensor-product-based algorithm for CFPQ. First of all, we reduce this algorithm to operations over Boolean matrices. All paths semantics. Previous matrix-based solution only single path. For both regular and context-free path queries. Correctness and time complexity.
- (2) We demonstrate interconnection between CFPQ and incremental transitive closure. Conjecture on sublinear incremental transitive closure and subcubic CFPQ. We show that incremental transitive closure is a bottleneck on the way to get subcubic CFPQ algorithm.
- (3) By using existing results we show how to get slightly subcubic algorithm for general case, and subcubic combinatorial algorithm for partial cases. This criterion is output-sensitive, so it is not practical, but open a theoretical way to find more subclass with subcubic complexity.
- (4) We implement the described algorithm and evaluate it on real-world data. RPQ, CFPQ. Results show that !!!

2 PRELIMINARIES

In this section we introduce basic notation and definitions from graph theory and formal language theory which are used in our work.

2.1 Language-Constrained Path Querying Problem

We use a directed edge-labeled graph as a data model. To introduce the *Language-Constraint Path Querying Problem* [?] over directed edge-labeled graphs we should give both language and grammar definitions.

First of all, we introduce edge-labeled digraph $\mathcal{G} = \langle V, E, L \rangle$, where V is a finite set of vertices, $E \subseteq V \times L \times V$ is a finite set of edges, L is a finite set of edge labels. Note that one can always introduce bijection between V and $Q = \{0, \dots, |V| - 1\}$, thus in our work we guess that $V = \{0, \dots, |V| - 1\}$.

The example of a graph which we will use in further examples is presented in Figure 1.

Figure 1: The example of input graph \mathcal{G}

Each edge-labeled graph can be represented as an adjacency matrix M : square $|V| \times |V|$ matrix, such that $M[i, j] = \{l \mid e = (i, l, j) \in E\}$. Adjacency matrix M_2 of the graph \mathcal{G} is

$$M_2 = \begin{pmatrix} \cdot & \{a\} & \cdot & \cdot \\ \cdot & \cdot & \{a\} & \cdot \\ \{a\} & \cdot & \cdot & \{b\} \\ \cdot & \cdot & \{b\} & \cdot \end{pmatrix}.$$

In our work we use decomposition of the adjacency matrix to a set of Boolean matrices:

$$\mathcal{M} = \{M^l \mid l \in L, M^l[i, j] = 1 \iff l \in M[i, j]\}.$$

Matrix M_2 can be represented as a set of two Boolean matrices M_2^a and M_2^b where

$$M_2^a = \begin{pmatrix} \cdot & 1 & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot \\ 1 & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \end{pmatrix}, M_2^b = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & 1 \\ \cdot & \cdot & 1 & \cdot \end{pmatrix} \quad (1)$$

In this way we reduce operations which are necessary for our algorithm from operations over custom semiring (over edge labels) to operations over a Boolean semiring.

Also, we should define the path in the graph and the word formed by the path.

Definition 2.1. Path π in the graph $\mathcal{G} = \langle V, E, L \rangle$ is a sequence e_0, e_1, \dots, e_{n-1} , where $e_i = (v_i, l_i, u_i) \in E$ and for any e_i, e_{i+1} $u_i = v_{i+1}$. We denote path from v to u as $v\pi u$.

Definition 2.2. The word formed by a path

$$\pi = (v_0, l_0, v_1), (v_1, l_1, v_2), \dots, (v_{n-1}, l_{n-1}, v_n)$$

is a concatenation of labels along the path: $\omega(\pi) = l_0 l_1 \dots l_{n-1}$.

The next part is a definitions from the formal language theory.

Definition 2.3. A language \mathcal{L} over a finite alphabet Σ is a subset of all possible sequences formed by symbols from the alphabet: $\mathcal{L}_\Sigma = \{\omega \mid \omega \in \Sigma^*\}$.

Now we are ready to introduce CFPQ problem for the given graph $\mathcal{G} = \langle V, E, L \rangle$ and the given language \mathcal{L} with reachability and all paths semantics.

Definition 2.4. To evaluate context-free path query with reachability semantics is to construct a set of pairs of vertices (v_i, v_j) such that there exists a path $v_i \pi v_j$ in \mathcal{G} which forms the word from the given language:

$$R = \{(v_i, v_j) \mid \exists \pi : v_i \pi v_j, \omega(\pi) \in \mathcal{L}\}$$

Definition 2.5. To evaluate context-free path query with all paths semantics is to construct a set of paths π in \mathcal{G} which form the word from the given language:

$$\Pi = \{\pi \mid \omega(\pi) \in \mathcal{L}\}$$

Note that Π can be infinite, thus in practice, we should provide a way of enumerating such paths with reasonable complexity, instead of explicit construction of the Π .

2.2 Regular Path Queries and Finite State Machine

The first case of language-constrained path querying is *Regular Path Querying* (RPQ): the language L is a regular language. This case is widely spread in practice [?].

Usual way to specify regular languages is *regular expressions*. We use the following definition of regular expressions.

Definition 2.6. Regular expression (and regular language) over alphabet Σ can be inductively defined as follows.

- \emptyset (empty language) is regular expression
- ε (empty string) is regular expression
- $a_i \in \Sigma$ is regular expression
- if R_1 and R_2 are regular expressions, then $R_1 \mid R_2$ (alternation), $R_1 \cdot R_2$ (concatenation), R_1^* (Kleene star) are also regular expressions.

For example, one can specify regular expression $R_1 = ab^*$ to find paths in the graph \mathcal{G} (fig. 1). Expected result is set of paths which start with a -labeled edge and contain zero or more b -labeled edges after that.

In this work we use the notion of *Finite-State Machine* (FSM) or *Finite-State Automaton* (FSA) for RPQs.

Definition 2.7. Deterministic Finite-State Machine T is a tuple $\langle \Sigma, Q, Q_s, Q_f, \delta \rangle$ where

- Σ is an input alphabet,
- Q is a finite set of states,
- $Q_s \subseteq Q$ is a set of start (or initial) states,
- $Q_f \subseteq Q$ is a set of final states,
- $\delta : Q \times \Sigma \rightarrow Q$ is a transition function.

It is well known, that every regular expression can be converted to deterministic FSM without ε -transitions. To do it one can use [15]. In our work we use FSM as a representation of RPQ. FSM can be naturally represented by a directed edge-labeled graph: $V = Q, L = \Sigma, E = \{(q_i, l, q_j) \mid \delta(q_i, l) = q_j\}$, where some vertices have special markers to specify start and final states. Example of graph-style representation of FSM T_1 for the regular expression R_1 is presented in Figure 2.

Figure 2: The example of graph representation of FSM for the regular expression ab^*

As a result, FSM also can be represented as a set of Boolean adjacency matrices \mathcal{M} with additional information about

start and final vertices. Such representation of T_1 is

$$M^a = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}, M^b = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

Note, that the edge-labeled graph is an FSM: edges are transitions, all vertices should be both start and final at the same time. Thus RPQ evaluation is an intersection of two FSMs, and the result also can be represented as FSM, because regular languages are closed under intersection.

2.3 Context-Free Path Querying and Recursive State Machines

An even more general case, than RPQ, is a *Context-Free Path Querying Problem (CFPQ)*, where one can use context-free languages as constraints. These constraints are more expressive than the regular ones, for example, one can express classical same-generation query using context-free language, but not a regular one.

Definition 2.8. Context-free grammar $G = \langle \Sigma, N, S, P \rangle$ where Σ is a finite set of terminals (or terminal alphabet), N is a finite set of nonterminals (or nonterminal alphabet), $S \in N$ is a start nonterminal, and P is a finite set of productions (grammar rules) of form $N_i \rightarrow \alpha$ where $N_i \in N$, $\alpha \in (\Sigma \cup N)^*$.

Definition 2.9. The sequence $\omega_2 \in (\Sigma \cup N)^*$ is derivable from $\omega_1 \in (\Sigma \cup N)^*$ in one derivation step, or $\omega_1 \rightarrow \omega_2$, in the grammar $G = \langle \Sigma, N, S, P \rangle$ iff $\omega_1 = \alpha N_i \beta$, $\omega_2 = \alpha \gamma \beta$, and $N_i \rightarrow \gamma \in P$.

Definition 2.10. Context-free grammar $G = \langle \Sigma, N, S, P \rangle$ specifies a *context-free language*: $\mathcal{L}(G) = \{\omega \mid S \xrightarrow{*} \omega\}$, where $(\xrightarrow{*})$ denotes zero or more derivation steps (\rightarrow) .

Thus, one can use the grammar $G_1 = \langle \{a, b\}, \{S\}, S, \{S \rightarrow a b; S \rightarrow a S b\} \rangle$ to find paths which form words in the language $\mathcal{L}(G_1) = \{a^n b^n \mid n > 0\}$ in the graph \mathcal{G} (fig. 1).

Regular expressions can be transformed to a FSM, and a context free grammar can be transformed to *Recursive State Machine (RSM)* (also known as recursive networks [?], recursive automata [?], !!!) in the similar way. In our work we use the following definition of RSM.

Definition 2.11. A recursive state machine R over a finite alphabet Σ is defined as a tuple of elements $(M, m, \{C_i\}_{i \in M})$, where:

- M is a finite set of labels of boxes.
- $m \in M$ is an initial box label.
- Set of *component state machines* or *boxes*, where $C_i = (\Sigma \cup M, Q_i, q_i^0, F_i, \delta_i)$:
 - $\Sigma \cup M$ is a set of symbols, $\Sigma \cap M = \emptyset$
 - Q_i is a finite set of states, where $Q_i \cap Q_j = \emptyset, \forall i \neq j$
 - q_i^0 is an initial state for C_i

- F_i is a set of final states for C_i , where $F_i \subseteq Q_i$
- $\delta_i : Q_i \times (\Sigma \cup M) \rightarrow Q_i$ is a transition function

RSM behaves as a set of finite state machines (or FSM). Each FSM is called a *box* or a *component state machine* [1]. A box works almost the same way as a classical FSM, but it also handles additional *recursive calls* and employs an implicit *call stack* to *call* one component from another and then return execution flow back.

The execution of an RSM could be defined as a sequence of the configuration transitions, which are done on input symbols reading. The pair (q_i, S) , where q_i is current state for box C_i and S is stack of *return states*, describes execution configurations.

The RSM execution starts from configuration $(q_m^0, \langle \rangle)$. The following list of rules defines the machine transition from configuration (q_i, S) to (q', S') on some input symbol a from input sequence, which is read as usual for FSA:

- $(q_i^k, S) \rightsquigarrow (\delta_i(q_i^k, a), S)$
- $(q_i^k, S) \rightsquigarrow (q_j^0, \delta_i(q_i^k, j) \circ S)$
- $(q_j^k, q_i^t \circ S) \rightsquigarrow (q_i^t, S)$, where $q_j^k \in F_j$

Some input sequence of the symbols $a_1 \dots a_n$, which forms some input word, is accepted, if machine reaches configuration $(q, \langle \rangle)$, where $q \in F_m$. It is also worth noting that the RSM makes nondeterministic transitions, without reading the input character when it *calls* some component or makes a *return*.

According to [1], recursive state machines are equivalent to pushdown systems. Since pushdown systems are capable of accepting context-free languages [15], it is clear that RSMs are equivalent to context-free languages. Thus RSMs suit to encode query grammars. Any CFG can be easily converted to an RSM with one box per nonterminal. The box which corresponds to a nonterminal A is constructed using the right-hand side of each rule for A .

An example of such RSM R constructed for the grammar G with rules $S \rightarrow aSb \mid ab$ is provided in Figure 3. For a given example of the grammar and the RSM consider the following sequence of the machine configuration transitions, in case, where one want to determine, if input word $aabb$ belongs to the language $\mathcal{L}(G)$. The RSM execution starts from configuration $(q_S^0, \langle \rangle)$, reads symbols a and goes to $(q_S^1, \langle \rangle)$. Then, in the nondeterministic manner it tries to read b but fails, and in the same time tries to derive S and goes to configuration $(q_S^0, \langle q_S^2 \rangle)$, where q_S^2 is *return* state. Then machine reads a and goes to $(q_S^1, \langle q_S^2 \rangle)$. In this case, in the nondeterministic choice it fails to derive S , but successfully reads b and goes to configuration $(q_S^3, \langle q_S^2 \rangle)$. Since q_S^3 is final state for the box S , the RSM tries to make *return* and goes to $(q_S^2, \langle \rangle)$. Then it reads b and transits to $(q_S^3, \langle \rangle)$. Since $q_S^3 \in F_S$ and the *return* stack is empty, the machine accepts the input sequence $aabb$.

Since R is a set of FSMs, it is useful to represent R as an adjacency matrix for the graph where vertices are states from $\bigcup_{i \in M} Q_i$ and edges are transitions between q_i^a and q_i^b with label $l \in \Sigma \cup M$, if $\delta_i(q_i^a, l) = q_i^b$. An example of such adjacency matrix M_R for the machine R is provided in section ??.

Figure 3: The recursive state machine R for grammar G

Similarly to a FSM, an RSM can be represented as a graph and, hence, as a set of Boolean adjacency matrices. For our example, M_1 is:

$$M_1 = \begin{pmatrix} \cdot & \cdot & \{a\} & \cdot \\ \cdot & \cdot & \{S\} & \{b\} \\ \cdot & \cdot & \cdot & \{b\} \\ \cdot & \cdot & \cdot & \cdot \end{pmatrix}$$

Matrix M_1 can be represented as a set of Boolean matrices as follows:

$$M_1^S = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & 1 & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \end{pmatrix}, M_1^a = \begin{pmatrix} \cdot & \cdot & 1 & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \end{pmatrix}, M_1^b = \begin{pmatrix} \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & 1 \\ \cdot & \cdot & \cdot & 1 \\ \cdot & \cdot & \cdot & \cdot \end{pmatrix}$$

Similarly to an RPQ, a CFPQ is the intersection of the given context-free language and a FSM specified by the given graph. As far as every context-free language is closed under intersection with regular languages, such intersection can be represented as an RSM. Also, one can look at the RSM as a FSM over $\Sigma \cup N$. In this work we use this point of view to propose unified algorithm for evaluation both regular and context-free path queries with zero overhead for regular ones.

2.4 Graph Kronecker Product and Machines Intersection

First of all, we introduce classical Kronecker product definition, describe graph Kronecker product and its relation to Boolean matrices algebra, RSM and FSM intersection.

Definition 2.12. Given two matrices A and B of sizes $m_1 \times n_1$ and $m_2 \times n_2$ respectively, with element-wise product operation \cdot . The Kronecker product of these two matrices is a new matrix $C = A \otimes B$, where:

- C has size $m_1 * m_2 \times n_1 * n_2$
- $C[u * m_1 + v, n_1 * p + q] = A[u, p] \cdot B[v, q]$

It is worth mention, that the Kronecker product produces blocked matrix C , with total number of the blocks $m_1 * n_1$, where each block has size $m_2 * n_2$ and is defined as $A[i, j] \cdot B$ (scalar to matrix).

Definition 2.13. Given two edge-labeled directed graphs $\mathcal{G}_1 = \langle V_1, E_1, L_1 \rangle$ and $\mathcal{G}_2 = \langle V_2, E_2, L_2 \rangle$ the Kronecker product of these two graphs is a edge-labeled directed graph $\mathcal{G} = \mathcal{G}_1 \otimes \mathcal{G}_2$, where $\mathcal{G} = \langle V, E, L \rangle$:

- $V = V_1 \times V_2$
- $E = \{((u, v), l, (p, q)) \mid (u, l, p) \in E_1 \wedge (v, l, q) \in E_2\}$
- $L = L_1 \cap L_2$

The Kronecker product for graphs produces a new graph with a nice property, that if some path $(u, v)\pi(p, q)$ exists in the result graph then paths $u\pi_1 p$ and $v\pi_2 q$ exist in the input graphs, and $\omega(\pi) = \omega(\pi_1) = \omega(\pi_2)$. These paths π_1 and π_2 could be easily found from π by its definition.

The Kronecker product for directed graphs can be easily described as the Kronecker product of the corresponding adjacency matrices of graphs, what gives us the following definition:

Definition 2.14. Given two adjacency matrices M_1 and M_2 of sizes $m_1 \times n_1$ and $m_2 \times n_2$ respectively, for some directed graphs \mathcal{G}_1 and \mathcal{G}_2 . The Kronecker product of these two adjacency matrices is the adjacency matrix M of a some graph \mathcal{G} , where:

- M has size $m_1 * m_2 \times n_1 * n_2$
- $M[u * m_1 + v, n_1 * p + q] = M_1[u, p] \cap M_2[v, q]$

By the definition, the Kronecker product for adjacency matrices gives an adjacency matrix with the same set of edges as in the resulting graph in the Def. 2.13. Thus, $M(\mathcal{G}) = M(\mathcal{G}_1) \otimes M(\mathcal{G}_2)$, where $\mathcal{G} = \mathcal{G}_1 \otimes \mathcal{G}_2$.

Definition 2.15. Given two FSMs $T_1 = \langle \Sigma, Q^1, Q_S^1, S_F^1, \delta^1 \rangle$ and $T_2 = \langle \Sigma, Q^2, Q_S^2, S_F^2, \delta^2 \rangle$. The intersection of this two machines is a new FSM $T = \langle \Sigma, Q, Q_S, S_F, \delta \rangle$, where:

- $Q = Q^1 \times Q^2$
- $Q_S = Q_S^1 \times Q_S^2$
- $Q_F = Q_F^1 \times Q_F^2$
- $\delta : Q \times \Sigma \rightarrow Q, \delta(\langle q_1, q_2 \rangle, s) = \langle q'_1, q'_2 \rangle,$
if $\delta(q_1, s) = q'_1$ and $\delta(q_2, s) = q'_2$

According to [15], the above definition of the FSM intersection allows to construct the new machine with the following property: $L(T) = L(T_1) \cap L(T_2)$.

The most computationally expensive part of such procedure is the δ function construction for the new machine T . Using adjacency matrices decomposition for FSMs we can reduce the intersection to the Kronecker product of such

matrices over Boolean semiring at some extent, since the transition function δ of the machine T in matrix form is exactly the same as the product result. More precisely:

Definition 2.16. Given two adjacency matrices \mathcal{M}_1 and \mathcal{M}_2 over Boolean semiring. The Kronecker product of these matrices is a new matrix $\mathcal{M} = \mathcal{M}_1 \otimes \mathcal{M}_2$, defined as follows:

- $\mathcal{M} = \{M_1^a \otimes M_2^a \mid a \in \Sigma\}$
- The element-wise operation is *and* over Boolean values

Applying the Kronecker product theory for both the FSM and the edge-labeled directed graph, we can intersect this objects as shown in Def. 2.16, since the graph could be interpreted as an FSM with transitions matrix represented as the adjacency matrix.

In this work we show how to express RSM and FSM intersection in terms of Kronecker product and transitive closure over Boolean semiring.

3 CONTEXT-FREE PATH QUERYING BY KRONECKER PRODUCT

In this section, we introduce the algorithm for CFPQ which is based on Kronecker product of Boolean matrices. The algorithm provides the ability to solve all-pairs CFPQ in all-path semantics (according to Hellings [?]) and consists of the two following parts.

- (1) Index creation. In the first step, the algorithm computes an index which contains information which is necessary to restore paths for specified pairs of vertices. This index can be used to solve the reachability problem without paths extraction. Note that this index is finite even if the set of paths is infinite.
- (2) Paths extraction. All paths for the given pair of vertices can be enumerated by using the index computed at the previous step. As far as the set of paths can be infinite, all paths cannot be enumerated explicitly, and advanced techniques such as lazy evaluation are required for implementation. Anyway, a single path can be always extracted by using standard techniques.

We describe both these steps, prove correctness, and provide time complexity estimations. For the first step we firstly introduce naïve algorithm. After that we show how to achieve cubic time complexity by using dynamic transitive closure algorithm and demonstrate that this technique allow us to get truly subcubic CFPQ algorithm for planar graphs.

After that we provide step-by-step example of query evaluation by using the proposed algorithm.

3.1 Index Creation Algorithm

The *index creation* algorithm outputs the final adjacency matrix \mathcal{M}_2 for the input graph with all vertices pairs, which are reachable through some nonterminal in the input grammar

G , and the index matrix C_3 , which allows to extract later paths in the *path extraction* algorithm.

The algorithm is based on the generalization of the FSM intersection for an RSM, and the edge-labeled directed input graph. Since the RSM is composed as set of FSMs, it could be easily presented as adjacency matrix for some graph over labels set $\Sigma \cup S$. As shown in the Def. 2.16 we can apply Kronecker product from Boolean matrices to *intersect* the RSM and the input graph to some extent. But the RSM contains the nonterminal symbols from N with additional *recursive calls* logic, what requires *transitive closure* step for such symbols extraction.

Applying the Kronecker product and transitive closure theory together, we get the idea of the algorithm: iterative Kronecker product evaluation for the RSM and the input graph, followed by transitive closure, nonterminal extraction and the update of the graph adjacency matrix.

3.1.1 Over Boolean Matrices Version. Listing 1 shows main steps of the algorithm. The algorithm accepts context-free grammar $G = (\Sigma, N, P)$ and graph $\mathcal{G} = (V, E, L)$ as an input. An RSM R is created from the grammar G . Note, that R must have no ε -transitions. \mathcal{M}_1 and \mathcal{M}_2 are the Boolean adjacency matrices for the machine R and the graph \mathcal{G} correspondingly.

Then for each vertex i of the graph \mathcal{G} , the algorithm adds loops with non-terminals, which allows deriving ε -word. Here the following rule is implied: each vertex of the graph is reachable by itself through an ε -transition. Since the machine R does not have any ε -transitions, the ε -word could be derived only if a state s in the box B of the R is both initial and final. This data is queried by the *getNonterminals* function for each state s .

The algorithm terminates when the matrix \mathcal{M}_2 stops changing. Kronecker product of matrices \mathcal{M}_1 and \mathcal{M}_2 is evaluated for each iteration. The result is stored in \mathcal{M}_3 as a Boolean matrix. Since we are interested only in the reachability of some vertices, there is no need to store a separate Boolean matrix for each label from $\Sigma \cup N$. Therefore, we can collapse it into one Boolean matrix \mathcal{M}'_3 , what is done in the next step. This matrix has the following property from its definition: if some vertices connected by some path in the matrix \mathcal{M}'_3 then these vertices are connected by one or many paths in the matrix \mathcal{M}_3 . The matrix \mathcal{M}_3 could be interpreted as an adjacency matrix for some directed graph without labels with the same set of the vertices, as in the graph formed by \mathcal{M}_3 .

For the given \mathcal{M}'_3 a C_3 transitive closure matrix is evaluated by the corresponding function call. Then the algorithm iterates over cells of the C_3 . For the pair of indices (i, j) , it computes s and f — the initial and final states in the recursive automata R which relate to the concrete $C_3[i, j]$ of the closure matrix. If the given s and f belong to the same box B

of R , $s = q_B^0$, and $f \in F_B$, then *getNonterminals* returns the respective nonterminal. Then for each such nonterminal the respective matrix of the graph adjacency matrix M_2 is updated and a new edge as a Boolean value in the appropriate cell is added.

The functions *getStates* and *getCoordinates* (see Listing 2) are used to map indices between Kronecker product arguments and the result matrix. The Implementation appeals to the blocked structure of the matrix C_3 , where each block corresponds to some automata and graph edge.

The algorithm returns the computed path extraction index C_3 and the updated matrix M_2 , which contains the initial graph \mathcal{G} data as well as data for nonterminals from N . If a cell $M_2^S[i, j]$ for any valid indices i and j and $S \in N$ contains $\{1\}$, then vertex j is reachable from vertex i in grammar G for nonterminal S .

LEMMA 3.1. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = \langle \Sigma, N, S, P \rangle$ be a grammar. Let $M_{2,(k)}$ be an adjacency matrix M_2 after the execution of some iteration $k \geq 0$ of the algorithm in Listing 1. Then for any valid indices i, j and for each nonterminal $A \in N$*

such that cell $M_{2,(k)}^A[i, j]$ contains $\{1\}$, the following statement holds: in the graph $\mathcal{G} \exists i\pi j : A \xrightarrow{} l(\pi)$.*

PROOF. (Proof by induction)

Basis: For $k = 0$ and the statement of the lemma holds, since $M_{2,(0)} = M_2$, where M_2 is adjacency matrix of the graph \mathcal{G} . The nonterminals, which allow to derive ε -word, are also added at algorithm preprocessing step, since each vertex of the graph is reachable by itself through an ε -transition.

Inductive step: Assume that the statement of the lemma holds for any $k \leq (p - 1)$ and show that it also holds for $k = p$, where $p \geq 1$.

For the algorithm iteration p the Kronecker product M_3, M'_3 and transitive closure C_3 are evaluated as described in the algorithm. By the properties of this operations, some edge $e = ((s, i), (f, j))$ exists in the directed graph, represented by adjacency matrix C_3 , if and only if $\exists s\pi'f$ in the RSM graph, represented by matrix M_1 , and $\exists i\pi j$ in graph, represented by $M_{2,(p-1)}$. Concatenated symbols along the path π' form some derivation string v , composed from terminals and non-terminals, where $v \xrightarrow{*} l(\pi)$ by the inductive assumption.

The new $\{1\}$ will be added to the cell $M_{2,(k)}^A[i, j]$ only if s and f are initial and final states of some box of the RSM corresponding to the non-terminal A . In this case, the grammar G has the derivation rule $A \rightarrow v$, and by the inductive assumption $v \xrightarrow{*} l(\pi)$. Therefore, $A \xrightarrow{*} l(\pi)$ and this completes the proof of the lemma. □

LEMMA 3.2. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = \langle \Sigma, N, S, P \rangle$ be a grammar. Let $M_{2,(k)}$ be an adjacency matrix M_2 after the execution of some iteration $k \geq 0$ of the algorithm in Listing 1. For any path $i\pi j$ in the graph \mathcal{G} with word $l = l(\pi)$ if exists the derivation tree of l from the nonterminal A of the grammar G with the height $h \leq k + 1$, then $M_{2,(k)}^A[i, j]$ contains $\{1\}$.*

PROOF. (Proof by induction)

Basis: Show that statement of the lemma holds for the $k = 0$. Matrix $M_{2,(0)} = M_2$ and edges of the graph \mathcal{G} contains only labels from L . Since the derivation tree of height $h = k + 1 = 1$ contains only one non-terminal A as a root and only symbols from $\Sigma \cup \varepsilon$ as leafs, for all paths, which form a word with derivation tree of the height $h = 1$, the corresponding nonterminals will be added to the $M_{2,(0)}^A[i, j]$ via preprocessing step. Thus, the lemma statement holds for the $k = 1$.

Inductive step: Assume that the statement of the lemma hold for any $k \leq (p - 1)$ and show that it also holds for $k = p$, where $p \geq 2$.

For the algorithm iteration p the Kronecker product M_3, M'_3 and transitive closure C_3 are evaluated as described in the algorithm. By the properties of this operations, some edge

$e = ((s, i), (f, j))$ exists in the directed graph, represented by adjacency matrix C_3 , if and only if $\exists s\pi'f$ in the RSM graph, represented by matrix M_1 , and $\exists i\pi j$ in graph, represented by $M_{2,(p-1)}$.

For any path $i\pi j$, such that exist derivation tree of height $h < p + 1$ for the word $l(\pi)$ with root non-terminal A , the cell $M_{2,(p)}^A[i, j]$ contains $\{1\}$ by inductive assumption.

Suppose, that exists derivation tree T of height $h = p + 1$ with the root non-terminal A for the path $i\pi j$. The tree T is formed as $A \rightarrow a_1..a_d, d \geq 1$ where $\forall x \in [1..d] a_x$ is sub-tree of height $h_x \leq p$ for the sub-path $i_x\pi_x j_x$. By inductive hypothesis, there exists path π_x for each derivation sub-tree, such that $i = i_1\pi_1 i_2..i_d\pi_d j_d = j$ and concatenation of these paths forms $i\pi j$, and the root nonterminals of this sub-trees are included in the matrix $M_{2,(p-1)}$.

Therefore, vertices $i_x \forall x \in [1..d]$ form path in the graph, represented by matrix $M_{2,(p-1)}$, with complete set of labels. Thus, new $\{1\}$ will be added to the cell $M_{2,(p)}^A[i, j]$ corresponding to the vertices i and j and nonterminal A . This completes the proof of the lemma. \square

THEOREM 3.3. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = \langle \Sigma, N, S, P \rangle$ be a grammar. Let M_2 be a result adjacency matrix after the execution of the algorithm in Listing 1. Then for any valid indices i, j and for each nonterminal $A \in N$ the following statement holds: the cell $M_{2,(k)}^A[i, j]$ contains $\{1\}$, if and only if there is a path $i\pi j$ in the graph \mathcal{G} such that $A \xrightarrow{*} l(\pi)$.*

PROOF. This theorem is a consequence of the Lemma 3.1 and Lemma 3.2. \square

THEOREM 3.4. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = \langle \Sigma, N, S, P \rangle$ be a grammar. The algorithm in Listing 1 terminates in finite number of steps.*

PROOF. The main *while-loop* in the algorithm is executed while graph adjacency matrix M_2 is changing. Since the algorithm only adds the edges with non-terminals from N , the maximum required number of iterations is $|N| \times |V| \times |V|$, where each component has finite size. This completes the proof of the theorem. \square

3.1.2 Application of Dynamic Transitive Closure. In this subsection we show how to reduce the time complexity of the algorithm in Listing 1 by avoiding redundant calculations.

It is easy to see that the most time-consuming steps in this algorithm are the Kronecker product and transitive closure computations. Recall that the matrix M_2 is always changed in incremental manner i. e. elements (edges) are added to M_2 (and are never deleted from it) on each iteration of the

Figure 4: The vertex j become reachable from the vertex u after the addition of edge (i, j) . Then the vertex v is reachable from u after inserting the edge (i, j) if v is reachable from j .

algorithm in Listing 1. So one does not need to recompute the whole product or transitive closure if an appropriate data structure is maintained.

To deal with the Kronecker product computation, we use the left-distributivity of the Kronecker product. Let \mathcal{A}_2 be a matrix with newly added elements and \mathcal{B}_2 be a matrix with the all previously found elements, such that $M_2 = \mathcal{A}_2 + \mathcal{B}_2$. Then by the left-distributivity of the Kronecker product we have $M_1 \otimes M_2 = M_1 \otimes (\mathcal{A}_2 + \mathcal{B}_2) = M_1 \otimes \mathcal{A}_2 + M_1 \otimes \mathcal{B}_2$. Notice that $M_1 \otimes \mathcal{B}_2$ is known and is already in the matrix M_3 and its transitive closure also is already in the matrix C_3 , because it was calculated on the previous iterations, so it is left to update some elements of M_3 by computing $M_1 \otimes \mathcal{A}_2$, which can be done in $O(|\mathcal{A}_2| |M_1|)$ time, where $|\mathcal{A}|$ denotes the number of non-zero elements in a matrix \mathcal{A} .

The fast computation of transitive closure can be obtained by using incremental dynamic transitive closure technique. We use an approach by Ibaraki and Katoh [16] to maintain dynamic transitive closure. The key idea of their algorithm is to recalculate reachability information only for those vertices, which become reachable after insertion of the certain edge (see Figure 4 for details). The algorithm is presented in Listing 3 (we have slightly modified it to efficiently track new elements of the matrix C_3).

Listing 3 The dynamic transitive closure procedure

```

1: function ADD( $C_3, i, j$ )
2:    $n \leftarrow$  Number of rows in  $C_3$ 
3:    $C'_3 \leftarrow$  Empty matrix of size  $n \times n$ 
4:   for  $u \neq 0 \in \text{checkCondition}(C_3, i, j)$  do
5:     newReachablePairs( $C_3, C'_3, u, j$ )
6:   return  $C'_3$ 
7: function CHECKCONDITION( $C_3, i, j$ )
8:    $A \leftarrow$  Empty array of size  $n$ 
9:   for  $u \in 0..n \mid u \neq j$  do  $\triangleright 1 \wedge 1 = 0 \wedge 0 = 1 \wedge 0 = 0; 0 \wedge 1 = 1$ 
10:     $A[u] = C_3[u, j] \wedge C_3[u, i]$ 
11:  return  $A$ 
12: function NEWREACHABLEPAIRS( $C_3, C'_3, u, j$ )
13:   $C'_3[u, v] = C_3[u, v] \wedge C_3[j, v] \quad \triangleright 1 \wedge 1 = 0 \wedge 0 = 1 \wedge 0 = 0;$ 
     $0 \wedge 1 = 1$ 
```

Final version of the modified algorithm from Listing 1 is shown in Listing 4.

Listing 4 Kronecker product based CFPQ using dynamic transitive closure

21:         $x, y \leftarrow \text{getCoordinates}(C'_3, i, j)$ 
22:         $M_2[x, y] \leftarrow M_2[x, y] \cup \text{getNonterminals}(R, s, f)$ 
23:         $A_2[x, y] \leftarrow A_2[x, y] \cup \text{getNonterminals}(R, s, f)$ 
24:  return  $M_2, C_3$ 

```

THEOREM 3.5. *Let $\mathcal{G} = (V, E, L)$ be a graph and $G = \langle \Sigma, N, S, P \rangle$ be a grammar. The algorithm from Listing 4 calculates a result matrices M_2 and C_3 in $O(n^3)$ time where $n = |V|$.*

PROOF. Let $|\mathcal{A}|$ be a number of non-zero elements in a matrix \mathcal{A} . Consider the total time which is needed for computing the Kronecker products. The elements of the matrices $\mathcal{A}_2^{(i)}$ are pairwise distinct on every i -th iteration of the algorithm therefore we have

$$\sum_i T(M_1 \otimes \mathcal{A}_2^{(i)}) = |M_1| \otimes \sum_i |\mathcal{A}_2^{(i)}| = |M_1| O(n^2)$$

operations in total.

Now we derive the time complexity of maintaining the dynamic transitive closure. Notice that C_3 has size of $O(n^2)$ so no more than $O(n^2)$ edges will be added during all iterations of the Algorithm. The function *checkCondition* from the Listing 3 takes $O(n)$ time for every inserted edge (i, j) . Thus we have $O(n^2 n) = O(n^3)$ operations in total. The function *newReachablePairs* requires $O(n)$ time for a given vertex u . This operation is performed for every pair (j, v) of vertices such that a vertex j became reachable from the vertex u . The vertex j become reachable from the vertex u (and accordingly the value of the matrix cell $C_3[u, j]$ becomes 1 from 0) only once during the entire computation, so the function

newReachablePairs will be executed at most $O(n^2)$ times for every u and hence $O(n^3)$ times in total for all vertices. Therefore $O(n^3)$ operations are performed to maintain dynamic transitive closure during all iteration of the algorithm from Listing 4.

Notice that the matrix C'_3 contains only new elements, therefore C_3 can be updated directly using only $|C'_3|$ operations and hence $O(n^2)$ operations in total. The same holds for cycle in line 18 of the algorithm from Listing 4, because operations are performed only for non-zero elements of the matrix $|C'_3|$. Finally, we have that the time complexity of the algorithm is $O(n^2) + O(n^3) + O(n^2) + O(n^2) = O(n^3)$. \square

3.1.3 Speeding up by a factor of $\log n$. In this subsection we use the Four Russians' trick to speed up the dynamic transitive closure algorithm from the Listing 3.

THEOREM 3.6. *The computation of transitive closure matrices can be done in $O(n^3/\log n)$ time when n^2 edges are added to the graph.*

PROOF. Consider the function *checkCondition* from the Listing 3. Its operations are equivalent to the element-wise (Hadamard) product of two vectors of size n , where multiplication operation is denoted as \wedge and has the following properties: $1 \wedge 1 = 0 \wedge 0 = 1 \wedge 0 = 0$ and $0 \wedge 1 = 1$. The first vector represents reachability of a given vertex i from other vertices $\{u_1, u_2, \dots, u_n\}$ of the graph and the second vector represents the same for a given vertex j . The function *newReachablePairs* also can be reduced to the computation of the Hadamard product of two vectors of size n for a given u_k . The first vector contains the information whether vertices $\{v_1, v_2, \dots, v_n\}$ of the graph are reachable from a given vertex u_k and the second vector represents the same for a given vertex j . The element-wise product of two vectors can be calculated naively in time $O(n)$ which gives the $O(n^3)$ time for maintaining the transitive closure. Thus, the time complexity of the transitive closure can be reduced by speeding up element-wise product of two vectors of size n .

To achieve this goal, we use the Four Russians' trick. Split each vector into $n/\log n$ parts of size $\log n$. Create a table S such that $S(a, b) = a \wedge b$ where $a, b \in \{0, 1\}^{\log n}$. This takes a time $O(n^2 \log n)$, since there are $2^{\log n} = n$ variants of Boolean vectors of size $\log n$ and hence n^2 pairs of vectors (a, b) in total, and each component takes $O(\log n)$ time. With table S , we can calculate product of two parts of size $\log n$ in constant time. There are $n/\log n$ such parts, so the element-wise product of two vectors of size n can be calculated in time $O(n/\log n)$ with $O(n^2 \log n)$ preprocessing. This gives us a dynamic transitive closure algorithm running in time $O(n^3/\log n)$: both of the functions *checkCondition* and *newReachablePairs* are evaluated no more than $O(n^2)$ times

Transitive closure calculation introduces one new path of length 2 (respective cell is filled).

$$C_3^1 = tc(M_3^1) =$$

	(0,0)	(0,1)	(0,2)	(0,3)	(1,0)	(1,1)	(1,2)	(1,3)	(2,0)	(2,1)	(2,2)	(2,3)	(3,0)	(3,1)	(3,2)	(3,3)

This path starts in the vertex (0, 1) and finishes in the vertex (3, 3). We can see, that 0 is a start state of RSM R and 3 is a final state of RSM R . Thus we can conclude that there exists a path between vertices 1 and 3 such that respective word is acceptable by R . As a result we can add the edge (1, S , 3) to the \mathcal{G} , namely we should update the matrix M_2^S .

Second iteration. Modified input graph contains edge with table S . From now !!!

```

Figure 6: Example of call stack trace

Index creation is finished. Onw can use it to unswer reachability queries, but for some problems it is necessary to restore paths. One can do it by using index created. Let for example we try to restore path from 2 to 2 derived from S .

To do it one should call `getPaths(2, 2, s)`. Partial trace of this call is presented below in figure 6. First, we convert vertices from grap to indeces in matrix and call `getPathsInner`. Separation vertex `pats={4}` and try to get patrs of paths going throw vertex with `id = 4`.

Expected path is returned, other paths calualtion Lazy evaluation is required.

The paths enumeration problem is actual here: ho can we enumerate paths with small delay.

4 IMPLEMENTATION DETAILS

Naïve algorithm is implemented (without dynamic transitive closure).

Linear algebra, GraphBLAS, parallel CPU.

Specific details. Sparsity parameters. How to express some steps efficiently.

Integration with RedisGraph.

Grammar is a file.

On paths extraction algorithm. I think that we should implement single path extraction, and paths without recursive calls. Lazy evaluation is not good idea for C implementation.

5 EVALUATION

Questions.

- (1) Compare classical RPQ algorithms and our algorithm
- (2) Compare other CFPQ algorithms and our algorithms
- (3) Investigate effect of grammar optimization

5.1 RPQ

In order to do smthg....

Dataset description, tools selection.

5.1.1 Dataset. Dataset for evaluation

We evaluate our solution on RPQs. We choose templates of the most popular RPQs which are presented in table ?? We generate !!! queries for each template.

5.1.2 Results. Results of evaluation

Index creation.

Paths extraction

5.1.3 Conclusion.

5.2 CFPQ

Comparison with matrix-based algorithm.

5.2.1 Dataset. Dataset for evaluation. It should be CFPQ_Data².

Same-generation queries, memory aliases.

5.2.2 Results. Results of evaluation.

Index creation.

Paths extraction.

5.2.3 Conclusion.

5.3 Grammar transformation

On query optimization.

Memory aliases.

Synthetic???

6 RELATED WORK

Language constrained path querying is a wide area !!!!

RPQ algorithms: derivatives [?], Glushkov [?], etc.!!!! [?] distributed, not linear algebra.

CFPQ algorithms: Hellings [?], Bradford [7], Azimov [?], Verbitskaya [?], Ciro [?], form static code analysis [?],

Subcubic CFPQ: Bradford, Chatterjee, For trees — partial cases, RSM-s — 4 Russians method, Smth else?

Implementation side. Linear algebra based approaches to evaluate queries (Datalog, SPARQL, etc) [?] Not focused on types of queries. Matrices, !!!! SPARQL !!!! Datalog !!!!

7 CONCLUSION AND FUTURE WORK

In this work we present an improved version of the tensor-based algorithm for CFPQ: we reduce the algorithm to operations over Boolean matrices, and we provide ability to extract all paths which satisfy the query. Moreover, the provided algorithm can handle grammars in EBNF, thus it does not require grammar to be in CNF transformation and avoids grammar explosion. As a result, the algorithm demonstrates practical performance not only on CFPQ queries, but also on RPQ ones, which shown by our evaluation. Thus, we provide universal linear algebra based algorithm for RPQ and CFPQ evaluation.

Also the algorithm opens a way to attack long-standing problem on subcubic CFPQ by reducing it to incremental transitive closure: *incremental transitive closure with $O(n^{1-\epsilon})$ update time which returns all new reachable pairs on each insertion, implies $O(n^{3-\epsilon})$ CFPQ algorithm.* In this work we prove $O(n^3/\log n)$ time complexity by providing $O(n/\log n)$ transitive closure algorithm.

Thus, the first task for the future is to find truly sublinear algorithm for incremental transitive closure or, as a first step, to improve logarithmic factor. Also, it is interesting to get improved bounds in partial cases. For example, fully dynamic transitive closure for planar graphs can be supported in $O(n^{2/3} \log n)$ time per update [24], and for undirected graph one can use *disjoint sets* which provide operations bounded by inverse Ackermann function. Can we use these facts to provide better CFPQ algorithm for respective partial cases? In the case of planarity it is interesting to investigate properties of the input graph and grammar which allow to preserve planarity during query evaluation.

On the other hand, provided reduction opens a way to investigate streaming graph querying. This way we can formulate the following questions.

- (1) Can we provide more detailed analysis of dynamic CFPQ queries, than provided in [6]?
- (2) Can we provide practical solution for CFPQ querying of streaming graphs?

²!!!!

(3) Can we improve existing solutions for RPQ of streaming graphs?

From a practical perspective, it is necessary to analyze the usability of advanced algorithms for dynamic transitive closure. In the current work we evaluate naïve implementation in which transitive closure recalculated on each iteration from scratch. In [14] it is shown that some of advanced algorithms for dynamic transitive closure can be efficiently implemented. Can one of these algorithms be efficiently parallelized and utilized in the proposed algorithm?

Also, it is necessary to evaluate GPGPU-based implementation. Experience in Azimov's algorithm shows that the utilization of GPGPUs allows one to improve performance because operations of linear algebra can be efficiently implemented on GPGPU [22, 25]. Moreover, for practical reason, it is interesting to provide a multi-GPU version of the algorithm and to utilize unified memory, which is suitable for linear algebra based processing of out-of-GPGPU-memory data and traversing on large graphs [11, 13].

In order to simplify the distributed processing of huge graphs, it may be necessary to investigate different formats for sparse matrices, such as HiCOO format [20].

Finally, it is necessary to provide a multiple-source version of the algorithm and integrate it with a graph database. RedisGraph³ [9] is a suitable candidate for this purpose. This database uses SuiteSparse—an implementation of GraphBLAS standard—as a base for graph processing. This fact allowed to Arseny Terkhov et.al. to integrate Azimov's algorithm to RedisGraph with minimal effort [25].
